## ABSTRACT

Progenitor cells in the adult pancreas are potential sources of endocrine beta cells for treating type 1 diabetes. Previously, we identified tri-potent progenitor cells in the adult (2–4 month-old) murine pancreas that were capable of self-renewal and differentiation into duct, acinar, and endocrine cells *in vitro*. These progenitor cells were named pancreatic colony-forming units (PCFUs). However, because PCFUs are a minor population in the pancreas (~1%) they are difficult to study. To enrich PCFUs, strategies using cell-surface marker analyses and fluorescence-activated cell sorting were developed. We found that CD133<sup>high</sup>CD71<sup>low</sup> cells, but not other cell populations, enriched PCFUs by up to 30 fold compared to the unsorted cells. CD133<sup>high</sup>CD71<sup>low</sup> cells generated primary, secondary, and subsequent colonies when serially re-plated in Matrigel-containing cultures, suggesting self-renewal abilities. In the presence of a laminin hydrogel, CD133<sup>high</sup>CD71<sup>low</sup> cells gave rise to colonies that contained duct, acinar, and Insulin<sup>+</sup> Glucagon<sup>+</sup> double-hormonal endocrine cells. Colonies from the laminin hydrogel culture were implanted into diabetic mice, and five weeks later duct, acinar, and Insulin<sup>+</sup> Glucagon<sup>+</sup> cells were detected in the grafts, demonstrating tri-lineage differentiation potential of CD133<sup>high</sup>CD71<sup>low</sup> cells. These CD133<sup>high</sup>CD71<sup>low</sup> cells will enable future studies of putative adult pancreas stem cells *in vivo*.

## 1. Introduction

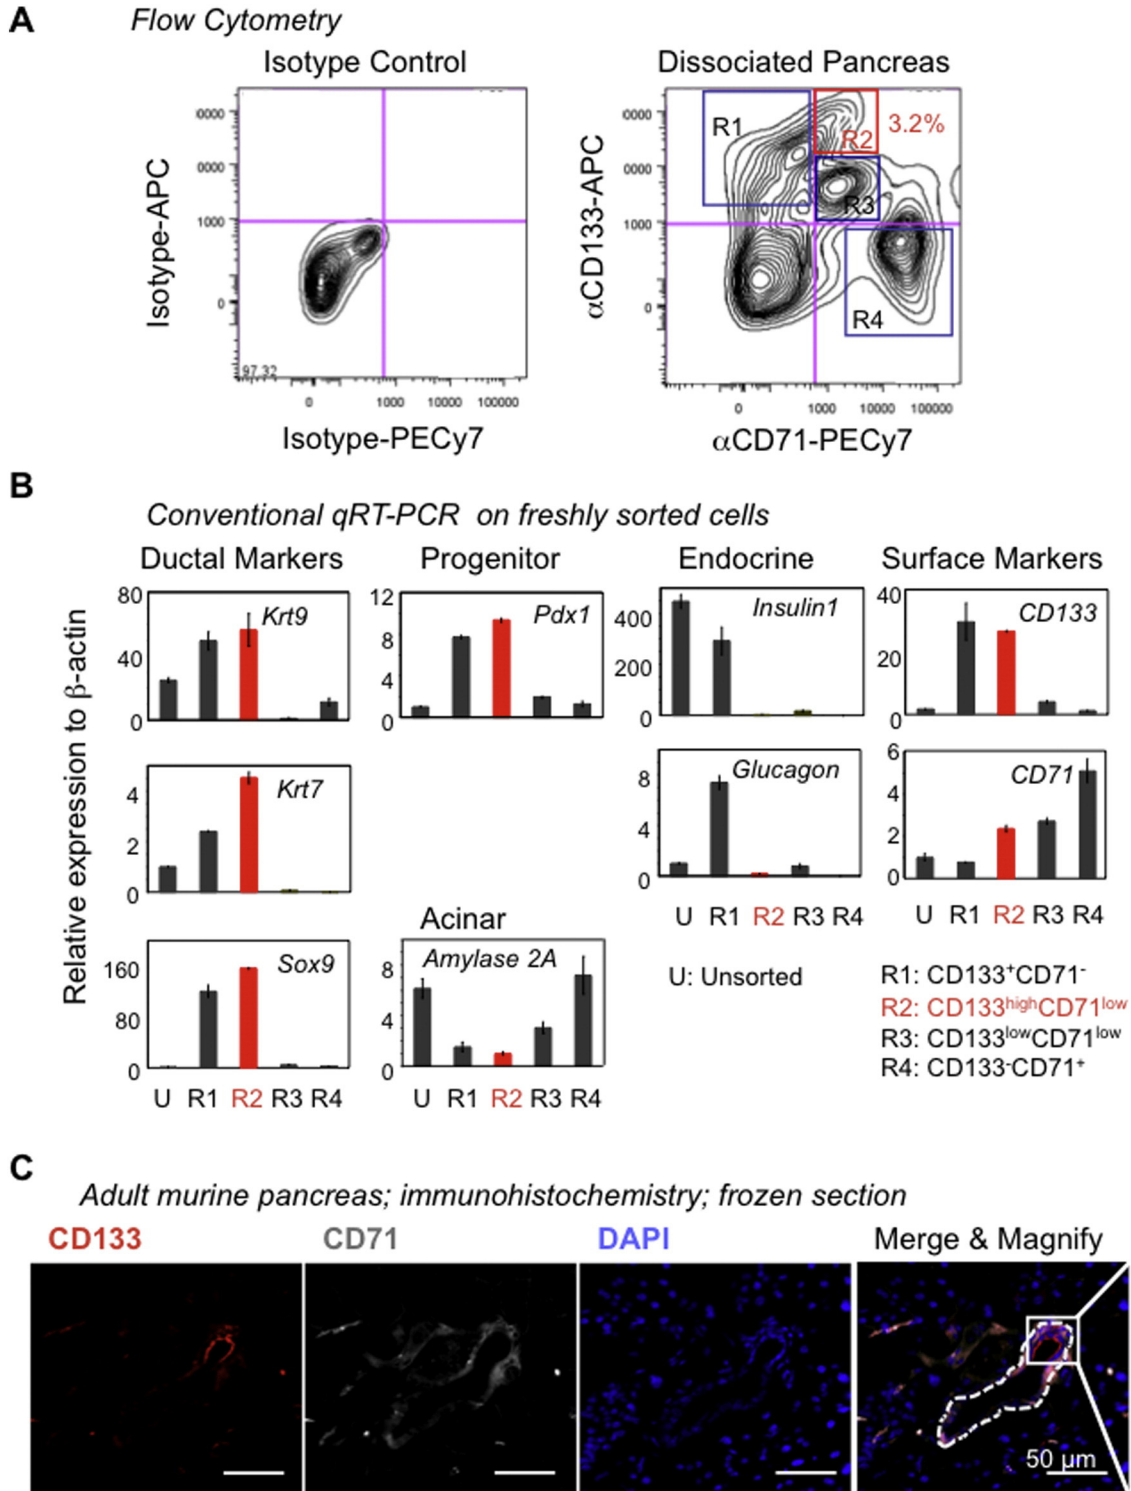

The pancreas plays a critical role in regulating metabolism and is composed of three major cell lineages: acinar cells, which secrete digestive enzymes such as amylase; duct cells, which transport digestive enzymes into the gut and secrete mucin to fend off pathogens; and endocrine cells, which secrete hormones such as insulin and glucagon that are important for glucose homeostasis.

Pancreas development follows a sequence of events regulated by transcription factors. Around embryonic day (E) 8.5, murine pancreatic endoderm expresses critical transcription factors, such as pancreas duodenal homeobox (Pdx) 1 and Sox9. Between E8.5 and E12.5, Pdx1<sup>+</sup> and Sox9<sup>+</sup> ductal cells are multi-potential and capable of giving rise to all three lineages in the adult pancreas (Gu et al., 2002; Zhou et al., 2007; Kopp et al., 2011). After E12.5, the lineage potential of the ductal epithelium becomes restricted (Gu et al., 2002; Zhou et al., 2007; Kopp et al., 2011), and the up-regulation of another key transcription factor,

neurogenin (Ngn) 3 is necessary for subsequent differentiation into endocrine cells (Apelqvist et al., 1999; Gradwohl et al., 2000).

There has been an intense debate about whether the adult pancreas harbors stem and progenitor cells that can give rise to new insulin-producing beta cells. Because of their roles as progenitors in the early

embryo, duct cells in the adult pancreas have long been the assumed source of new beta cells (Bonner-Weir et al., 2004). However, in mouse models using Cre-Lox lineage-tracing techniques, contradictory results either positively (Inada et al., 2008; Xu et al., 2008) or negatively (Kopp et al., 2011; Dor et al., 2004; Furuyama et al., 2011; Kopinke &

**Fig. 1.** CD133 and CD71 are expressed in the adult murine pancreas. (A) Flow cytometry analyses of dissociated pancreatic cells stained with antibodies against CD133 and CD71. CD71 sub-fractionates CD133-expressing ductal cells, suggesting heterogeneity of ductal cells. (B) Regions (R) 1 to 4 indicated in (A) were analyzed for gene expression by conventional qRT-PCR. (C) Double immunohistochemical staining on frozen sections showed that CD133 and CD71 expressions were located mostly in the ductal structures (outlined by a dotted line) in the adult murine pancreas. (D) Immunohistochemical staining on adjacent slides prepared from formalin-fixed, paraffin-embedded pancreas. Both primary antibodies for Sox9 and CD71 were rabbit antibodies. Results showed that Sox9<sup>+</sup> ductal regions were also positive for CD71 staining. (E) Double immunostaining on frozen sections showed that Pdx1 protein was expressed in the CD133<sup>+</sup> ductal cells with various intensities. The yellow arrow indicates a CD133<sup>+</sup> duct cell expressing a higher level of Pdx1 than other duct cells. (F) Representative genes identified from RNA-seq analyses which are significantly up-regulated in R2 versus R1 cells.

**Fig. 1** (continued).

Murtaugh, 2010; Teta et al., 2007; Solar et al., 2009) implicate ducts as the source of progenitor cells in the adult pancreas. In addition to ducts, cells expressing markers for acinar (Ptf1a (Pan et al., 2013; Baeyens et al., 2014), carboxypeptidase A (Zhou et al., 2008), or elastase (Baeyens et al., 2014)) or endocrine cells (insulin (Dor et al., 2004) or glucagon (Thorel et al., 2010)) have been shown to give rise to new beta cells in the adult murine pancreas. Together, these results suggest that there are multiple mechanisms by which beta cells can be replenished from different cellular sources in the adult pancreas. However, the aforementioned *in vivo* lineage-tracing studies did not directly address properties of multi-potentiality and self-renewal—two criteria necessary to define a stem cell.

To investigate progenitor cells in the adult pancreas, we and others have turned to *in vitro* single cell analysis. We designed unique 3D colony assays that allow quantitative analyses of single progenitor-like cells from adult murine pancreas. Using these assays, we found that the adult murine pancreas contains tripotent progenitor cells that are capable of multi-lineage differentiation and robust self-renewal *in vitro* (Jin et al., 2013; Fu et al., 2013; Jin et al., 2014). These progenitor-like cells were named “pancreatic colony-forming units” (PCFUs). Consistent with our findings, other laboratories confirmed that dissociated single cells from the adult pancreas of mice (Huch et al., 2013; Dorrell et al., 2014) and humans (Lee et al., 2013) can be propagated in high concentrations (>33% vol/vol) of Matrigel *in vitro* where they generate

cystic “organoid” colonies similar to what we observed (Jin et al., 2013; Fu et al., 2013; Jin et al., 2014). Together, these results demonstrate that single cells with the capacities for self-renewal and multi-lineage differentiation *in vitro* are present in the adult pancreas. However, these PCFU progenitor cells remain poorly characterized.

One major roadblock to effective characterization of PCFUs is that they constitute a minor population in the adult pancreas (~1% in 2–4 month-old mice) (Jin et al., 2013; Jin et al., 2014). Thus, purification of these progenitor cells is needed. Previously, a transgenic mouse model was used for enrichment of PCFUs (Jin et al., 2013). In this mouse model, expression of enhanced green fluorescence protein (EGFP) reporter was driven by Sox9 regulatory loci (75 kb upstream and 150 kb downstream sequences) in a CD1 out-bred background (Formeister et al., 2009). However, this strategy prohibits enrichment of PCFUs from other mouse models. Therefore, identification of cell surface markers expressed by PCFUs could lead to an alternative enrichment method. CD133 (prominin 1) is a cell-surface marker commonly used to enrich various stem cells from adult tissues (Miraglia et al., 1997), and adult pancreatic ducts of humans and mice express CD133 (Hori et al., 2008; Lardon et al., 2008; Oshima et al., 2007; Sugiyama et al., 2007). Our prior work demonstrated that CD133<sup>+</sup>, but not CD133<sup>−</sup> pancreatic cells from adult C57Bl/6 (B6) mice, contained PCFUs (Jin et al., 2013; Jin et al., 2014). However, only one in about twenty pancreatic CD133<sup>+</sup> cells was a PCFU (Jin et al., 2014), consistent with a recent report (Dorrell et al., 2014).

The goal of this study was to identify an additional cell-surface marker that, when combined with CD133, could further distinguish and enrich PCFUs. Cell surface markers that were previously known to enrich non-pancreas progenitor cells, including CD71 (transferrin receptor), were screened. CD71 transports iron from the extracellular space into cells, and higher levels of CD71 expression are detected in erythroid progenitor cells (Fraser et al., 2007) as well as in some cancer cells (Keysar & Jimeno, 2010). The adult pancreas expresses CD71 (Gatter et al., 1983); however, its role in the pancreas has not been characterized. Here, we report that CD71 expression status fractionates pancreatic CD133<sup>+</sup> ductal cells in adult mice. Among the subpopulations, CD133<sup>high</sup>CD71<sup>low</sup> cells are the most enriched for PCFUs, and approximately one in three CD133<sup>high</sup>CD71<sup>low</sup> cells is a PCFU. This enriched population will enable further studies on putative pancreas stem and progenitor cells *in vivo*.

## 2. Results

### 2.1. Expression of CD133 and CD71 in the adult murine pancreas

CD133 is expressed by the ductal cells of the adult pancreas (Hori et al., 2008; Lardon et al., 2008; Oshima et al., 2007; Sugiyama et al., 2007). We used flow cytometry analysis to screen other known cell-surface markers to determine their ability to fractionate adult CD133<sup>+</sup> pancreatic cells. CD71 was found to divide CD133<sup>+</sup> ductal cells into three major subpopulations: CD133<sup>+</sup>CD71<sup>−</sup>, CD133<sup>high</sup>CD71<sup>low</sup>, and CD133<sup>low</sup>CD71<sup>low</sup> cells, as indicated by regions (R) 1 to 3, respectively (Fig. 1A), suggesting heterogeneity of ductal cells.

Quantitative (q) RT-PCR analysis of freshly sorted cells indicated that cells in both R1 and R2 expressed higher levels of ductal genes (*Krt19*, *Krt7* and *Sox9*) and *Pdx1* compared to unsorted cells (Fig. 1B). Compared to R2, R1 cells expressed higher levels of endocrine markers, *Insulin1* and *Glucagon* (Fig. 1B). Because the lower limit of the R1 gate was close to the double negative cells, some endocrine cells may have been contaminated during sorting. In the subsequent RNA-seq experiments (see below), the lower boundary of the sorting gate for R1 was moved upward, and as a result no difference in the expression of *Insulin1* and *Glucagon* between R1 and R2 cells was observed (Supplementary Table 1). R3 cells did not express significant levels of the aforementioned pancreatic lineage markers (Fig. 1B).

To further confirm the expression of CD71 in the ducts, immunohistochemical staining on sections of adult murine pancreas was performed. As expected, CD133 was expressed in the ductal structures (Fig. 1C; dotted line). CD71 was found to co-localize with CD133 in the ducts (Fig. 1C). For additional confirmation, ductal cells that expressed Sox9 also stained positive for CD71 (Fig. 1D), again demonstrating that CD71 was expressed in the ductal region.

Pdx1 protein was detected in the CD133<sup>+</sup> ductal cells by double immunostaining analyses (Fig. 1E), although the overall intensities of Pdx1 was lower in ducts compared to that in the islet cells, which are known to express Pdx1 (Ohlsson et al., 1993). Interestingly, the staining intensities for Pdx1 or CD133 varied among individual ductal cells (Fig. 1E), again suggesting heterogeneity of ductal cells.

To further characterize R1 and R2 ductal cells, genome-wide gene expression analysis using RNA-seq was performed (Supplementary Fig. 1A). Compared to R1, R2 cells expressed higher levels of several ductal and epithelial cell markers including *Krt19* (Fig. 1F), consistent with the above qRT-PCR analysis (Fig. 1B). R2 cells expressed higher levels of *cyclin A2*, a positive regulator of cell cycle gene (Fig. 1F), suggesting that R2 cells may be ready for proliferation and forming colonies. Indeed, R2 but not R1 ductal cells gave rise to colonies in culture (see below). Pathway analysis of the RNA-seq data revealed that R2 and R1 cells have propensities for cell migration and immune response, respectively (Supplementary Fig. 1B). Taken together, these results demonstrate that, unlike the Sox9/EGFP mice used in our previous study (Jin et al., 2013), CD71 expression status fractionates pancreatic CD133<sup>+</sup> ductal cells into subpopulations in adult mice and that ductal cells are heterogeneous.

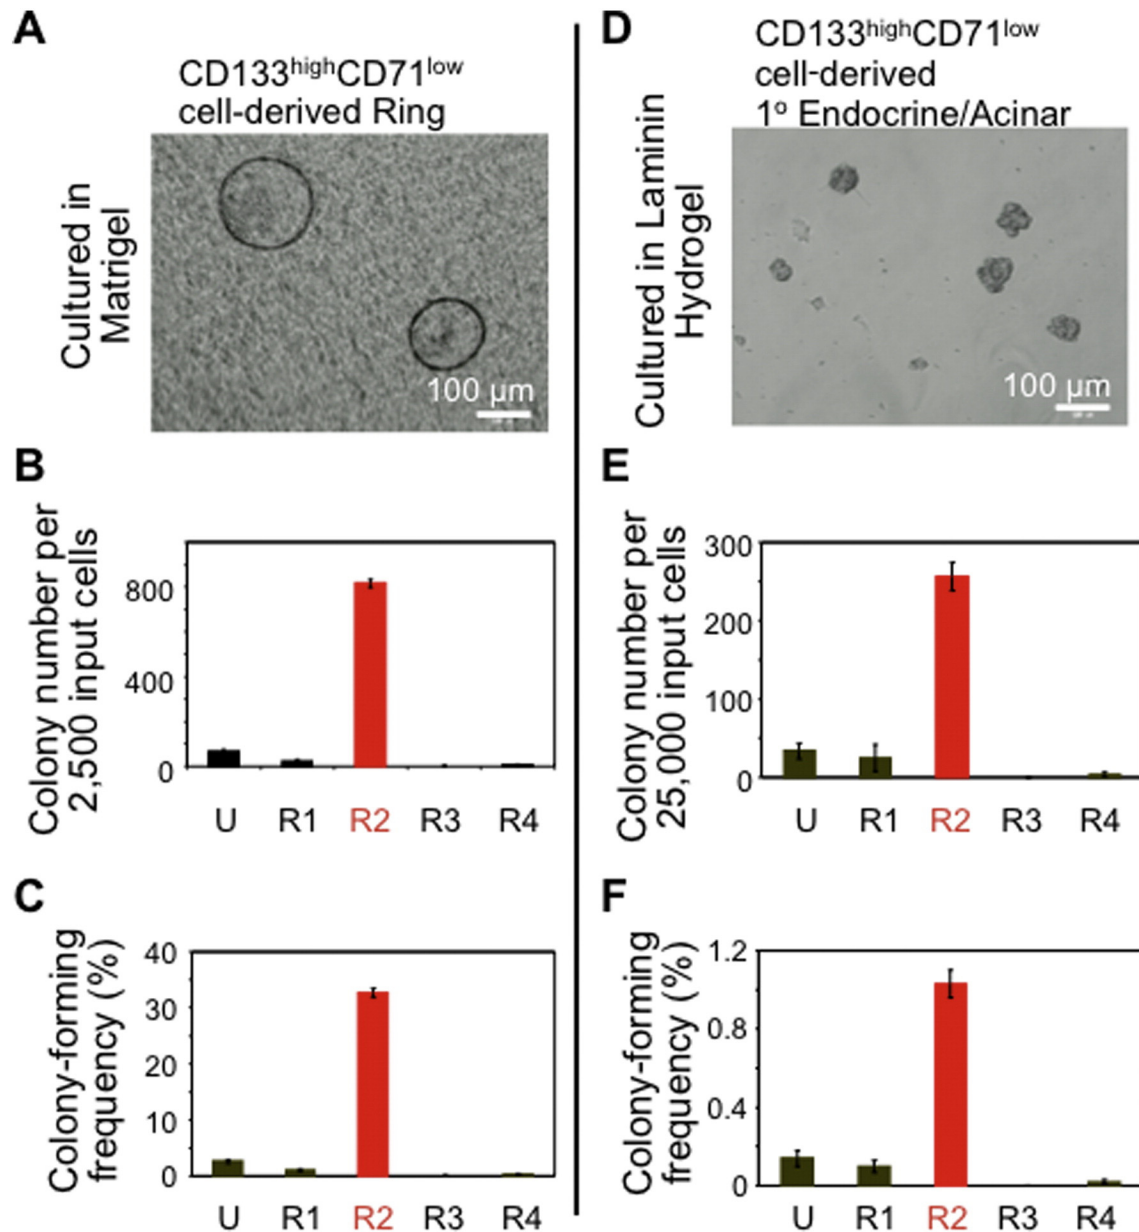

Most CD133<sup>−</sup> cells expressed CD71 at higher levels (Fig. 1A; R4) or at undetectable levels (double negative cells). Approximately 80% of CD133<sup>−</sup>CD71<sup>high</sup> (R4) cells expressed TER119 (Supplementary Fig. 2), an erythroid lineage-specific marker (Okada et al., 1991), suggesting that R4 contains mostly red blood cells or their immediate precursors. Red blood cells were lysed before antibody staining and flow cytometry analysis. This manipulation resulted in a reduced percentage of CD133<sup>−</sup>CD71<sup>high</sup> (R4) cells (Supplementary Fig. 3), further confirming that R4 contains red blood cells.

### 2.2. Murine adult pancreatic CD133<sup>high</sup>CD71<sup>low</sup> (Region 2) cells are most enriched for colony-forming progenitors

Previously, we devised two pancreatic colony assays, one containing Matrigel and the other a laminin hydrogel, which support the formation of Ring or Endocrine/Acinar colonies, respectively (Supplementary Fig. 4) (Jin et al., 2013). These colony types are morphologically distinct. Ring colonies are cystic and contain mostly ductal-like cells (Jin et al., 2013; Jin et al., 2014); whereas, Endocrine/Acinar colonies are small and compact, composed mostly of endocrine- and acinar-like cells and fewer ductal cells (Jin et al., 2013). A single progenitor cell capable of giving rise to a Ring or an Endocrine/Acinar colony is designated as a PCFU-Ring or a PCFU-Endocrine/Acinar, respectively.

Next, we tested which subpopulations contained PCFUs-Ring or PCFUs-Endocrine/Acinar (Fig. 2). Freshly sorted cells were plated into Matrigel or laminin hydrogel colony assays, and the resulting colonies were counted. CD133<sup>−</sup>CD71<sup>−</sup> cells did not form Ring or Endocrine/Acinar colonies, consistent with our previous studies showing that CD133<sup>−</sup> cells are devoid of PCFUs (Jin et al., 2013; Jin et al., 2014). In contrast, after three weeks in Matrigel colony assay, a plating of 2500 CD133<sup>high</sup>CD71<sup>low</sup> (R2) cells resulted in  $816 \pm 19$  Ring colonies (Fig. 2A & B), demonstrating that  $32 \pm 1\%$  of the CD133<sup>high</sup>CD71<sup>low</sup> cells were PCFUs-Ring (Fig. 2C).

In our previous studies, Endocrine/Acinar colonies formed when freshly-sorted CD133<sup>+</sup>Sox9/EGFP<sup>+</sup> cells were first expanded in Matrigel for 3 weeks to generate Ring colonies, which were subsequently dissociated and re-plated into laminin hydrogel for 10 days (Jin et al., 2013). These Endocrine/Acinar colonies grown in the secondary laminin-

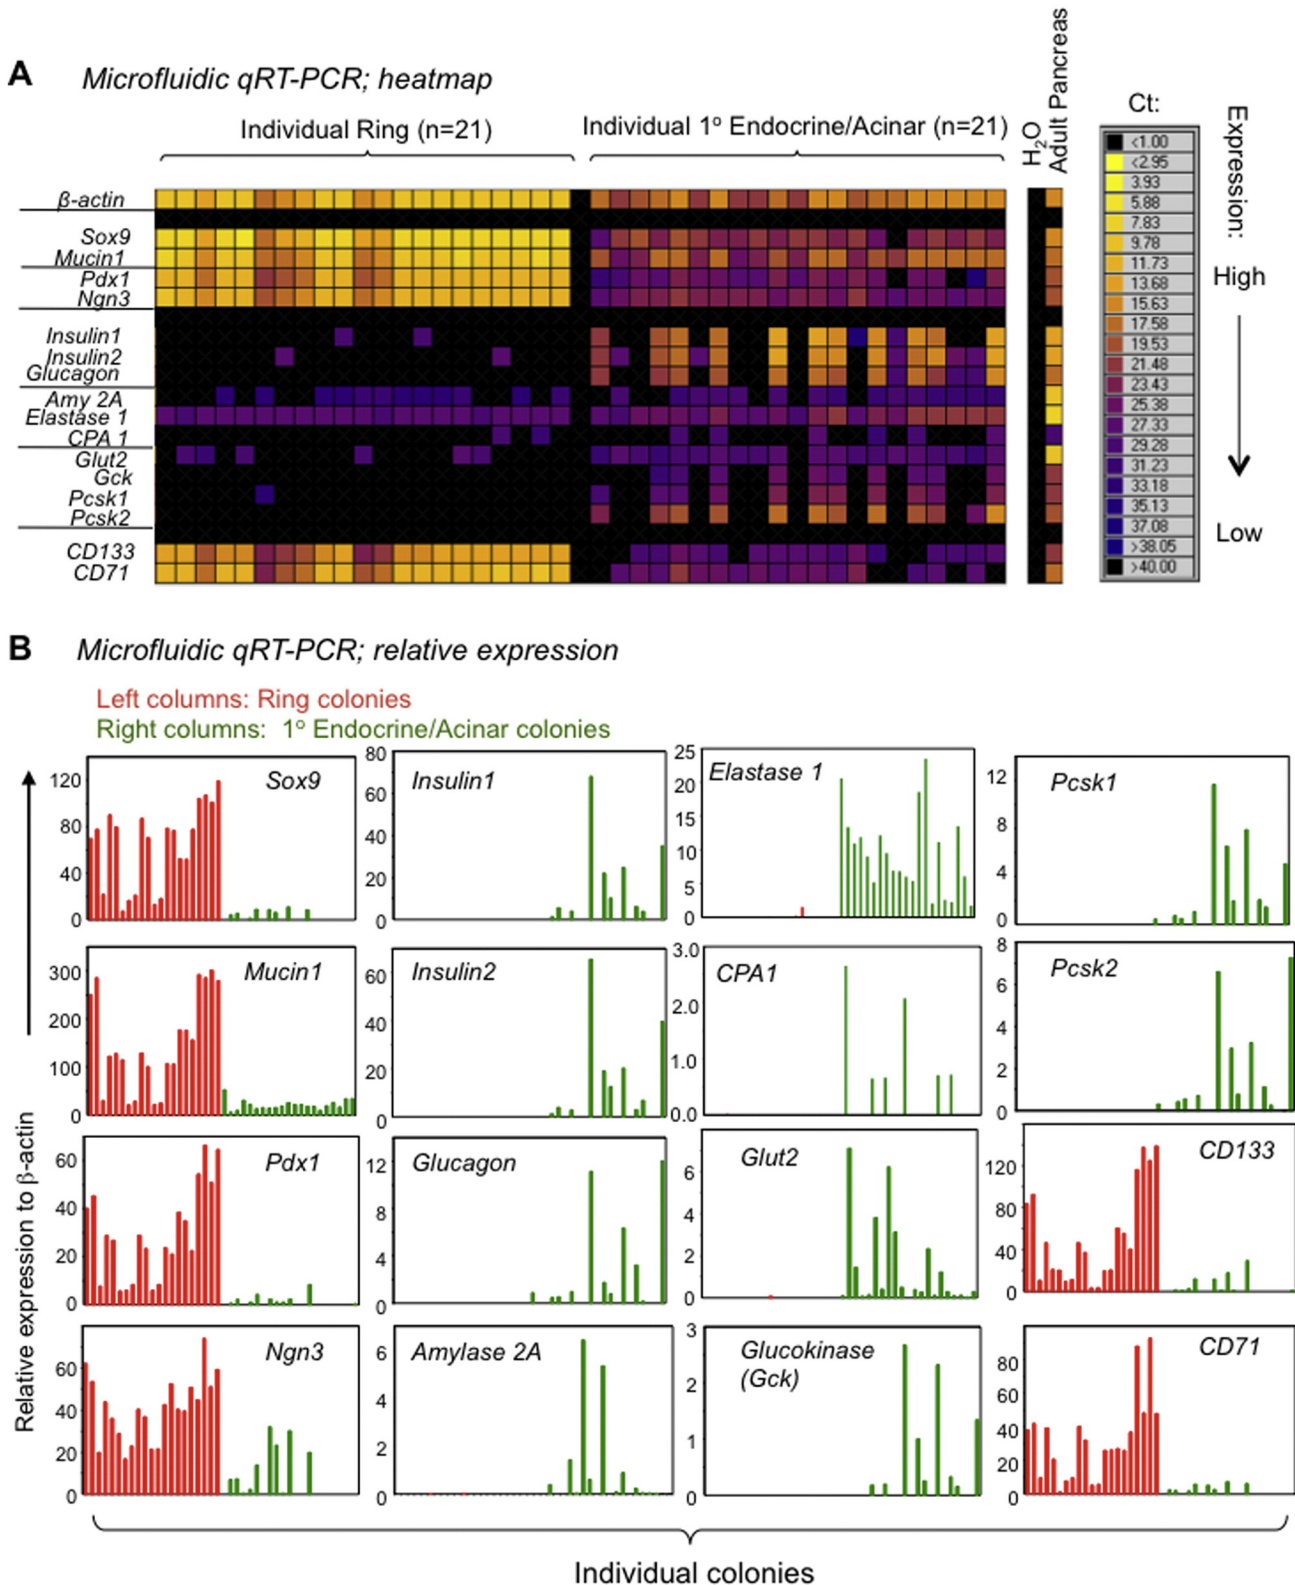

**Fig. 2.** The CD133<sup>high</sup>CD71<sup>low</sup> subpopulation is most enriched for colony-forming progenitor cells. (A & D) Photomicrographs of representative Ring (A) or 1° Endocrine/Acinar (D) colonies viewed under a phase-contrast microscope with visible light illumination. (B & C) Sorted R1 to R4 cells, as indicated in Fig. 1A, were plated into the Matrigel colony assay. After 3 weeks, the resulting Ring colonies were counted and the colony-forming efficiency (number of colonies divided by the total number of cells plated) determined. Data represent mean and standard deviation from triplicate wells. (E & F) Same as in B & C, except that sorted cells were plated in the laminin-hydrogel colony assay. Endocrine/Acinar colonies were counted 10 days post-plating.

hydrogel culture were designated as secondary (2°) Endocrine/Acinar colonies. Similarly, 2° Endocrine/Acinar colonies formed after Ring colonies derived from CD133<sup>high</sup>CD71<sup>low</sup> cells were dissociated and re-plated into laminin hydrogel (Supplementary Fig. 5). When sorted CD133<sup>high</sup>CD71<sup>low</sup> cells were directly plated into the laminin-hydrogel assay at 25,000 cells per well, 256  $\pm$  18 Endocrine/Acinar colonies were detected (Fig. 2D & E). These Endocrine/Acinar colonies grown in the primary laminin-hydrogel culture were designated as primary (1°) Endocrine/Acinar colonies. The colony-forming efficiency of CD133<sup>high</sup>CD71<sup>low</sup> (R2) cells for 1° Endocrine/Acinar colonies was 1  $\pm$  0.1% (Fig. 2F). In contrast, R1, R3 and R4 cells did not have significant colony-forming capacity compared to unsorted cells (Fig. 2B & E). Together, these results demonstrate that both PCFUs-Ring and 1° PCFUs-Endocrine/Acinar progenitors are enriched in the CD133<sup>high</sup>CD71<sup>low</sup> (R2) cell fraction. The CD133<sup>high</sup>CD71<sup>low</sup> (R2) cells represented 2.4  $\pm$  1.9% (n = 7; ranges 0.6–6.0%) of total dissociated pancreatic cells.

### 2.3. Ring colonies derived from the CD133<sup>high</sup>CD71<sup>low</sup> (R2) cells are ductal-like, express progenitor markers, and contain self-renewing colony-forming cells

To test the lineage compositions of individual Ring or 1° Endocrine/Acinar colonies, microfluidic qRT-PCR analyses were performed (Fig. 3A & B). Microfluidic qRT-PCR has a reaction volume in the nano-liter range, permitting gene expression analysis from a single colony (Jin et al., 2013; Narsinh et al., 2011). Colonies were individually handpicked under direct microscope visualization (n = 21 per group). Expression of a panel of genes indicative of pancreatic progenitor, ductal, endocrine, and acinar lineages was analyzed.

Individual Ring colonies expressed higher levels of ductal (Sox9 and Muc1) and progenitor cell markers (Ngn3 and Pdx1) (Fig. 3A & B), compared to 1° Endocrine/Acinar colonies. Transmission electron microscopy revealed multi-lobed nuclei (arrow) and microvilli (arrow

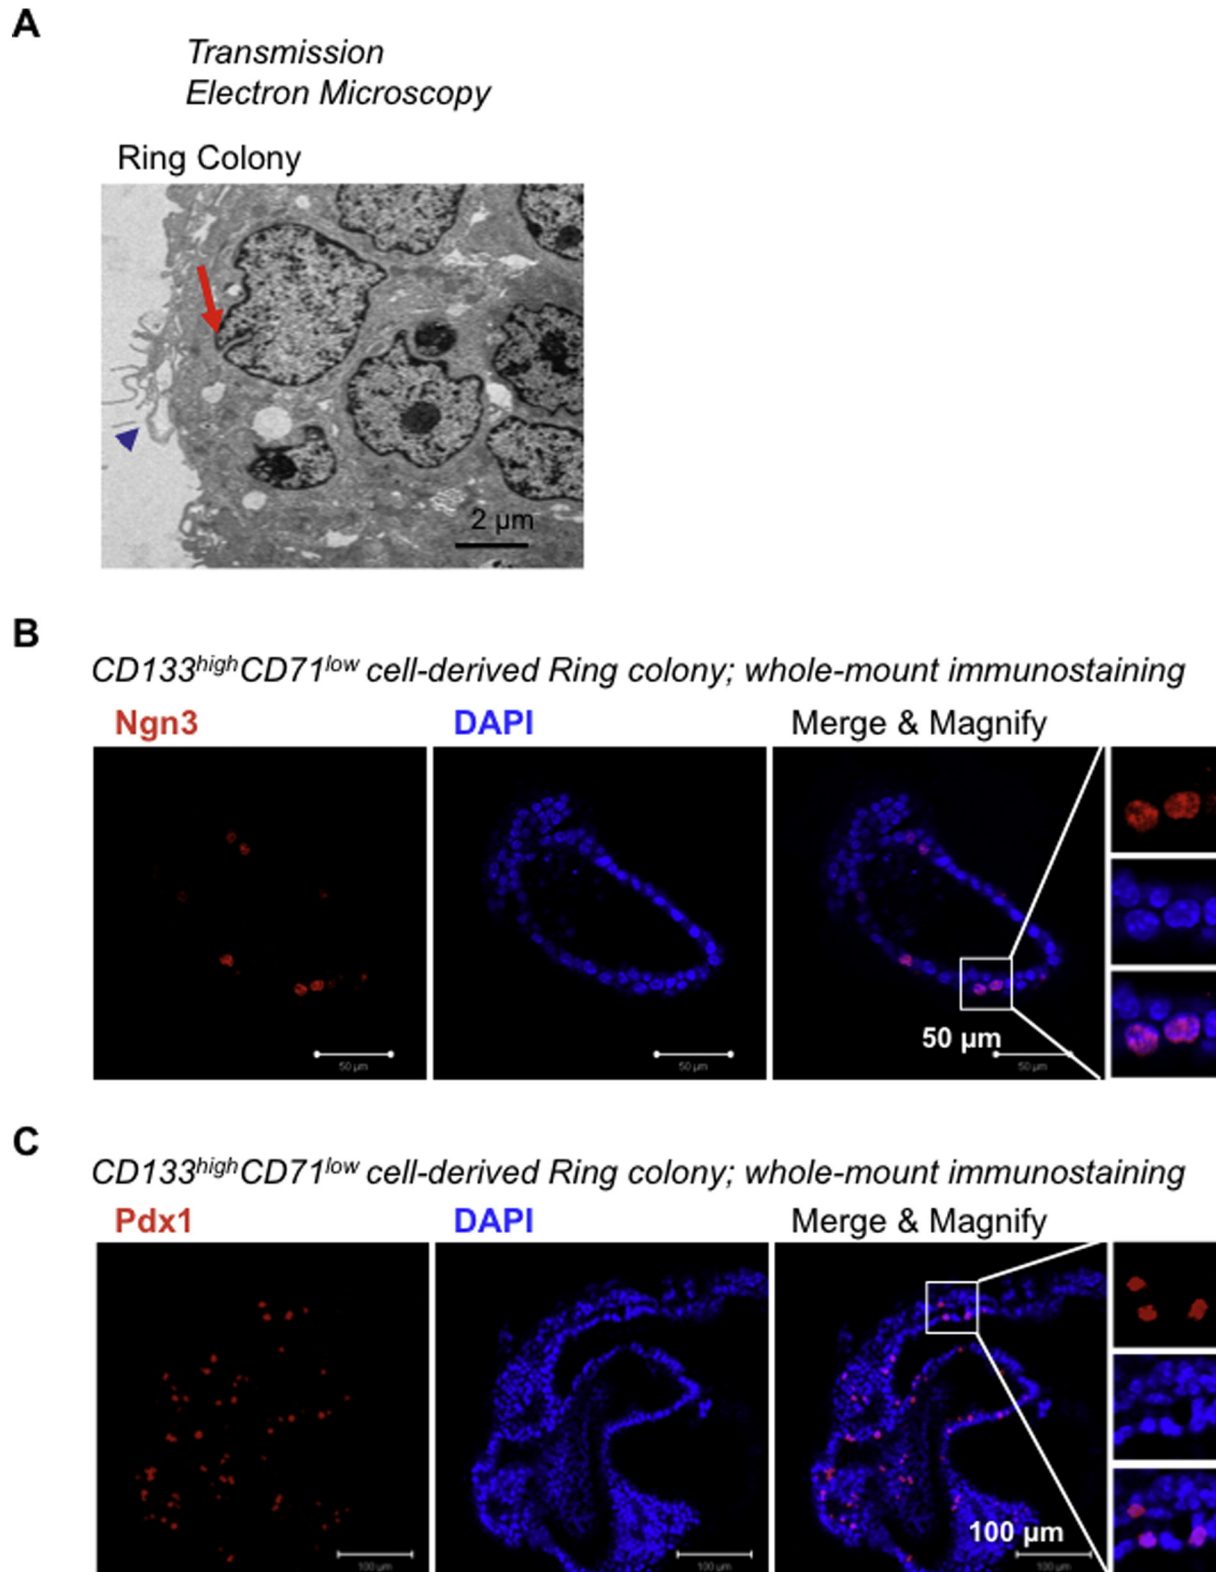

**Fig. 3.** CD133<sup>high</sup>CD71<sup>low</sup> cell-derived Ring or 1° Endocrine/Acinar colonies express higher levels of duct and progenitor or endocrine and acinar cell markers, respectively. (A & B) Microfluidic qRT-PCR analyses on individually handpicked colonies. The results in (A) are expressed as heat maps; whereas, (B) shows expression levels relative to  $\beta$ -actin. Each column or bar represents a single colony.

head) (Fig. 4A), indicating a ductal cell phenotype. Whole-mount immunostaining analysis confirmed protein expression of Ngn3 and Pdx1 in Ring colonies derived from CD133<sup>high</sup>CD71<sup>low</sup> (R2) cells (Fig. 4B & C; nucleus staining). These results are consistent with our prior findings

that Ring colonies, derived either from CD133<sup>+</sup>Sox9/EGFP<sup>+</sup> from CD1 outbred mice (Jin et al., 2013) or CD133<sup>+</sup> cells from B6 inbred mice (Jin et al., 2014), are predominantly ductal-like cells that express progenitor cell markers.

**Fig. 4.** Cells in Ring colonies display ultra-structures consistent with ductal phenotype, and some cells express progenitor markers. (A) Transmission electron microscopy of a Ring colony derived from CD133<sup>high</sup>CD71<sup>low</sup> cells. Arrow indicates indentation of the nuclear membrane. Arrow head indicates microvilli. These fine structures are ductal characteristics. (B & C) Whole-mount immunostaining of pooled Ring colonies showing protein expression of Ngn3 (B) and Pdx1 (C).

Three-week-old Ring colonies continued to express CD133 and CD71 (Fig. 3A & B), suggesting that the originating CD133<sup>high</sup>CD71<sup>low</sup> (R2) cells may have either given rise to ductal cells or self-renewed as progenitors. To test whether the freshly sorted CD133<sup>high</sup>CD71<sup>low</sup> (R2)

cells could self-renew, 3-week-old primary Ring colonies (n = 8) were individually handpicked, dissociated, and re-plated into Matrigel assays for a total of six passages (Fig. 5). All eight primary Ring colonies initiated secondary and subsequent colonies (Fig. 5), indicating that

single PCFUs-Ring contained in the CD133<sup>high</sup>CD71<sup>low</sup> (R2) population were capable of self-renewal *in vitro*.

#### 2.4. Primary “Endocrine/Acinar” colonies derived from the CD133<sup>high</sup>CD71<sup>low</sup> population express higher levels of endocrine and acinar markers, and lower levels of ductal markers compared to Ring colonies

In contrast to Ring colonies, 1° Endocrine/Acinar colonies expressed higher levels of endocrine (*Insulin1*, *Insulin2*, *Glucagon*) and acinar (*Amylase 2A*) genes, and lower levels of ductal (*Sox9*, *Mucin1*) genes in single-colony RT-PCR analyses (Fig. 3A & B). Protein expression of Amylase (an acinar marker) (Fig. 6A) in whole-mounted 1° Endocrine/Acinar colonies was detected but did not co-localize with C-peptide<sup>+</sup> cells (a surrogate marker for *de novo* synthesized insulin). Similarly, Krt19-expressing ductal cells did not co-stain with insulin (Fig. 6B). Surprisingly, double immunostaining of glucagon and C-peptide in 1° Endocrine/Acinar colonies revealed that cells expressing C-peptide were all positive for glucagon (Fig. 6C; yellow color). This is in contrast to our prior results on the 2° Endocrine/Acinar colonies that express single hormones (Jin et al., 2013). Transmission electron microscopy showed both insulin-like and non-insulin granules within cells in CD133<sup>high</sup>CD71<sup>low</sup> (R2)-derived 1° Endocrine/Acinar colonies (Fig. 6D), further confirming the double-hormonal phenotype.

CD133<sup>high</sup>CD71<sup>low</sup> (R2)-derived 1° Endocrine/Acinar colonies expressed higher levels of several beta cell maturation markers, such as *Glut2*, *Glucokinase*, *Pcsk1* and *Pcsk2*, compared to Ring colonies (Fig. 3A & B). Therefore, we tested whether these 1° Endocrine/Acinar colonies were glucose responsive in C-peptide secretion *in vitro* (Fig. 6E). Pooled (~1000) 1° Endocrine/Acinar colonies released 1.43-fold more C-peptide into the media when presented with 16.7 mM compared to 2.5 mM D-glucose (Fig. 6E). When colonies were bathed with 16.7 mM D-glucose plus 10 mM theophylline (a cAMP potentiator), 2.13-fold more C-peptide was released (Fig. 6E). Intracellular C-peptide levels in these colonies ( $0.65 \pm 0.32 \mu\text{g/g}$  proteins) were ~3700 fold lower than that in adult murine islets ( $2427 \pm 1395 \mu\text{g/g}$  proteins). Thus, despite the simultaneous expression of insulin and glucagon as well as the low intracellular C-peptide levels, CD133<sup>high</sup>CD71<sup>low</sup> (R2)-derived 1° Endocrine/Acinar colonies are functional in C-peptide secretion *in vitro*.

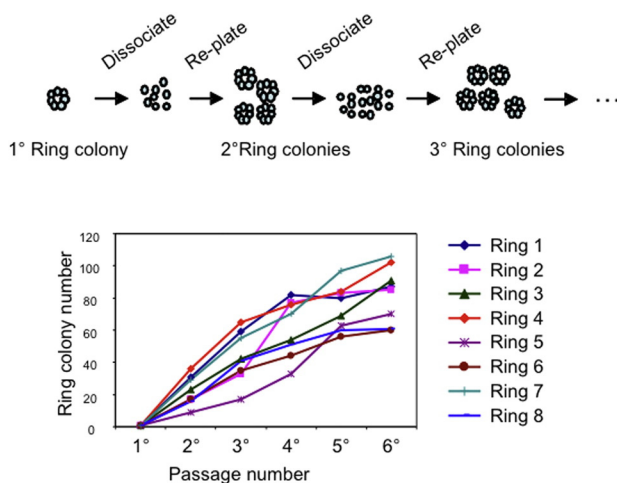

#### 2.5. Primary Endocrine/Acinar colonies give rise to ductal, acinar, C-Peptide<sup>+</sup> Glucagon<sup>−</sup>, and C-Peptide<sup>−</sup> Glucagon<sup>+</sup> cells *in vivo*

Attempts to dissociate and re-plate 1° Endocrine/Acinar colonies into 2° laminin hydrogel culture did not result in the formation of 2° Endocrine/Acinar colonies. In the positive control experiment, dissociated Ring colonies did form 2° Endocrine/Acinar colonies. These results suggest that the current laminin hydrogel culture condition may not support the development of the 2° Endocrine/Acinar colonies from the 1° Endocrine/Acinar colonies. To test whether an *in vivo* environment may allow further development of pancreatic lineages, 10-day-old 1° Endocrine/Acinar colonies were placed underneath the renal capsules of streptozotocin-induced diabetic mice (~12,000 colonies per kidney; n = 2). The grafts were examined 5 weeks post-transplantation (Fig. 7A). By week 5, cells were either insulin<sup>+</sup> glucagon<sup>−</sup> or insulin<sup>−</sup> glucagon<sup>+</sup> as shown by immunohistochemical staining (Fig. 7B). In addition, Krt19<sup>+</sup> ductal cells and Amylase<sup>+</sup> acinar cells were also detected in the grafts (Fig. 7B). The ductal-like cells were most likely originated from donor cells because they were located inside the grafts (Fig. 7A, H&E staining and Fig. 7B, blue box); however, further confirmation is required because kidney tubules are known to express KRT19 (Skinnider et al., 2005). Taken together, these results demonstrate that 1° Endocrine/Acinar colonies derived from the CD133<sup>high</sup>CD71<sup>low</sup> population have tri-lineage differentiation potential *in vivo* and are capable of giving rise to insulin<sup>+</sup> glucagon<sup>−</sup> cells.

### 3. Discussion

We report that sorting for CD133<sup>high</sup>CD71<sup>low</sup> cells enriches PCFU progenitors that form Ring or 1° Endocrine/Acinar colonies in Matrigel or laminin hydrogel, respectively. The enrichment of these PCFUs is achieved using a strategy that has been successful in purifying adult hematopoietic stem cells (HSCs) (Spangrude et al., 1988). Murine HSCs are often designated as lineage negative (Lin<sup>−</sup>), indicating that they do not express the cell-surface markers CD4, CD8, B220, Mac-1, Gr-1, or TER119 for differentiated blood cells (Spangrude et al., 1988). Additional markers, including stem cell antigen (Sca-1) (Spangrude et al., 1988), CD117 (c-Kit) (Okada et al., 1991), CD48, and CD150 (Kiel et al., 2005), have been identified to either positively or negatively select HSCs. About one in two Lin<sup>−</sup> Sca-1<sup>+</sup> c-kit<sup>+</sup> CD48<sup>−</sup> CD150<sup>+</sup> bone marrow cells is a HSC (Kiel et al., 2005).

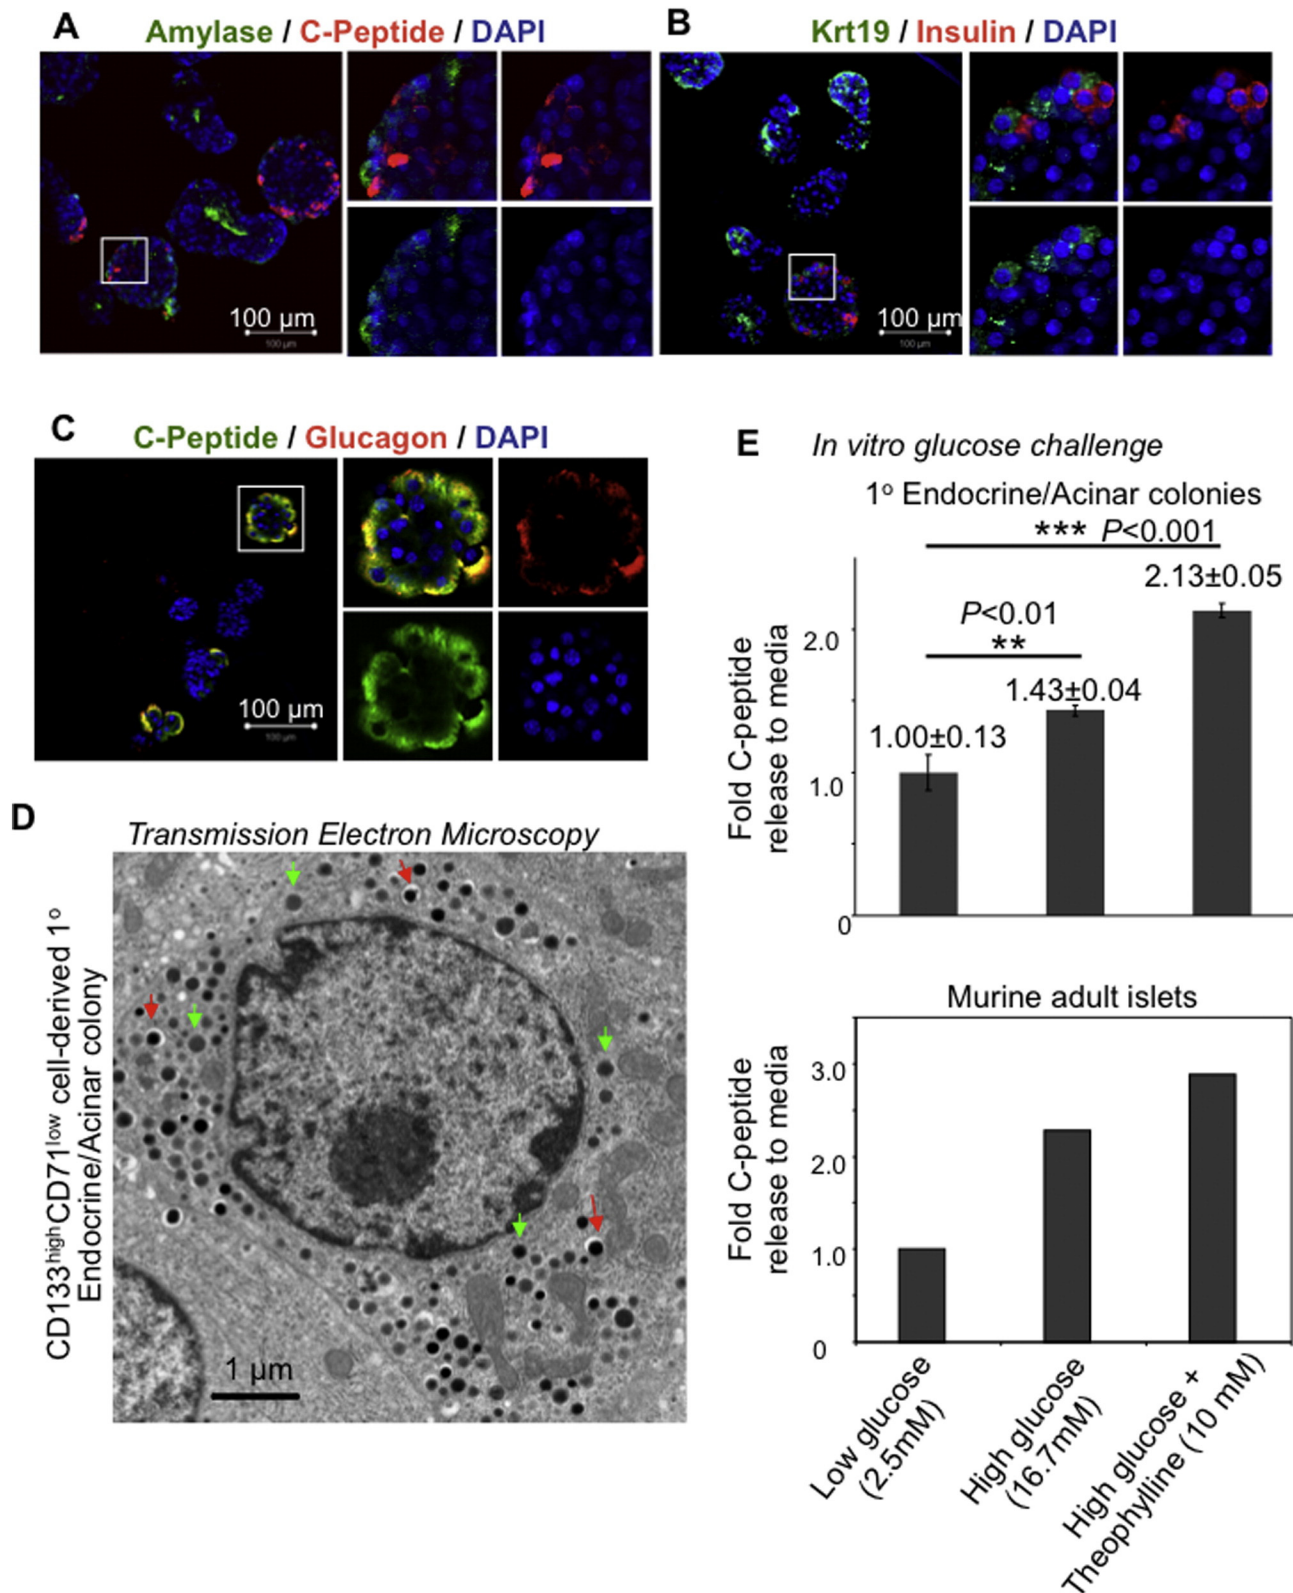

CD133 has been shown to positively enrich progenitors from embryos and neonates of murine (Hori et al., 2008; Oshima et al., 2007; Sugiyama et al., 2007; Ghazalli et al., 2015) and human (Sugiyama et al., 2007) pancreas, as well as from adult human pancreas (Lee et al., 2013). We (Jin et al., 2014) and others (Dorrell et al., 2014) have previously shown that pancreatic progenitor cells from adult mice can be enriched by CD133 selection. However, the cell culture techniques reported by others were more difficult to enumerate colonies. Cells were mixed in high concentrations (>33% vol/vol) of Matrigel and placed only at the edge of the culture well. After solidification, the Matrigel was thicker at the periphery than towards the center of the culture dish. When viewed under a phase-contrast light microscope, the images of the resulting colonies were largely overlapping, preventing effective counting. Quantification of colony was achieved by sparse organoid plating or single cell deposition methods (Dorrell et al., 2014), which were labor-intensive and resource-consuming. In contrast, the methylcellulose-containing semi-solid media that we used allowed us to evenly spread Matrigel and colonies across the culture well. In addition, a grid was attached underneath the culture well to further facilitate accurate numeration by avoiding double counting (Winkler et al., 2011). Using our quantitative assays, we find that approximately one in three adult pancreatic CD133<sup>high</sup>CD71<sup>low</sup> cells is a PCFU-Ring (Fig. 2C), compared to ~1 in 100 pre-sorted pancreatic cells (Jin et al., 2013; Jin et al., 2014) (Fig. 2C), which translates to a 33-fold enrichment. The efficiency of formation of Ring colonies from

**Fig. 5.** Single PCFU-Ring self-renews and generates secondary and subsequent Ring colonies *in vitro*. Upper panel: A schematic representation of a re-plating experiment. Sorted CD133<sup>high</sup>CD71<sup>low</sup> cells were plated into Matrigel-containing culture. Three weeks later, a primary Ring colony was hand-picked, dissociated into single cell suspension, and re-plated into Matrigel-containing culture for a total of 6 passages. Lower panel: Serial replating of an individually hand-picked primary Ring colony (n = 8) generated secondary and subsequent Ring colonies in Matrigel-containing culture.

*CD133<sup>high</sup>CD71<sup>low</sup> cell-derived 1° Endocrine/Acinar colonies; whole-mount immunostaining*

**Fig. 6.** Primary Endocrine/Acinar colonies express acinar, ductal, and endocrine markers and are glucose responsive *in vitro*. (A–C) Whole-mount immunostaining of 10-day-old 1° Endocrine/Acinar colonies. Note that C-peptide-expressing cells also express glucagon. (D) Transmission electron microscopy of a cell in a 1° Endocrine/Acinar colony that contained two types of granules. Red and green arrows indicate insulin-like and non-insulin granules, respectively. (E) Primary Endocrine/Acinar colonies were pooled and subjected to sequential *in vitro* incubation with designated levels of D-glucose and/or theophylline, a cAMP potentiator. Murine adult islets are positive controls.

Five weeks post-transplantation in diabetic mice

**B** Immunofluorescent staining; formalin-fixed paraffin-embedded graft

C-Peptide / Glucagon / DAPI

Amylase / Krt19 / DAPI

**Fig. 7.** Primary Endocrine/Acinar colonies give rise to acinar, ductal,  $insulin^{+}glucagon^{-}$ , and  $insulin^{-}glucagon^{+}$  cells in diabetic mice. (A) Left: Photomicrograph of a kidney 5 weeks after transplantation of 12,000 1° Endocrine/Acinar colonies. Right: Hematoxylin & Eosin (H & E) staining of the graft. (B) Double immunohistochemical staining of the graft with antibodies against C-peptide and Glucagon or Amylase and Krt19.

CD133<sup>high</sup>CD71<sup>low</sup> cells has now reached ~30% (Fig. 2C), compared to ~5% from CD133<sup>+</sup> selection alone in B6 mice (Jin et al., 2014) and ~15% from CD133<sup>+</sup>Sox9/EGFP<sup>+</sup> cells from CD1 mice (Jin et al., 2013). Importantly, the use of commercially-available antibodies rather than transgenic mice will enable the characterization of adult PCFUs in many laboratories.

The efficiency of formation of 1° Endocrine/Acinar colonies from unsorted pancreatic cells is only ~0.1% (Fig. 2F). CD133<sup>high</sup>CD71<sup>low</sup> cells enrich 1° PCFUs-Endocrine/Acinar about 8-fold compared to unsorted cells (Fig. 2F), and the colony-forming efficiency for 1° Endocrine/Acinar colonies from CD133<sup>high</sup>CD71<sup>low</sup> cells reaches ~1% (Fig. 2F).

As mentioned, Ring colonies in our previous studies developed from sorted CD133<sup>+</sup> (Jin et al., 2014) or CD133<sup>+</sup>Sox9/EGFP<sup>+</sup> cells (Jin et al., 2013). Consistent with the characteristics of those colonies, the Ring colonies derived from CD133<sup>high</sup>CD71<sup>low</sup> cells also express higher levels of ductal (Fig. 3B) and pancreatic progenitor cell markers, such as Pdx1 or Ngn3 (Fig. 3B), compared to 1° Endocrine/Acinar colonies. Similar to previous results (Jin et al., 2014), cells from a handpicked Ring colony derived from CD133<sup>high</sup>CD71<sup>low</sup> cells generate secondary and subsequent Ring colonies over six serial passages in Matrigel (Fig. 5), demonstrating the capacity for self-renewal of the originating, single PCFU-Ring.

A new observation from the current study is that cells in 10-day-old 1° Endocrine/Acinar colonies grown in laminin hydrogel express insulin and glucagon simultaneously (Fig. 6C and D). This is in contrast to the insulin<sup>+</sup>glucagon<sup>−</sup> or insulin<sup>−</sup>glucagon<sup>+</sup> cells in the 2° Endocrine/Acinar colonies that we identified in a previous report (Jin et al., 2013). Previously, freshly sorted CD133<sup>+</sup>Sox9/EGFP<sup>+</sup> cells were initially plated into the Matrigel assay, with or without exogenous R-spondin1, a Wnt signaling agonist, for 3 weeks to generate Ring colonies. When Ring colonies were collected and dissociated into single cell suspension and re-plated into laminin hydrogel for an additional 10 days, the 2° Endocrine/Acinar colonies that formed expressed either insulin or glucagon (Jin et al., 2013). These results suggest that our former two-step culture method, in which the PCFUs were expanded prior to the induction of endocrine differentiation, permitted more time for the progenitor cells to develop and mature into single hormonal positive cells. The 1° Endocrine/Acinar colonies derived from freshly sorted CD133<sup>+</sup>Sox9/EGFP<sup>+</sup> cells were not examined in the previous study (Jin et al., 2013) because of the low incidence of 1° Endocrine/Acinar colonies.

Five weeks post-transplantation into diabetic mice, CD133<sup>high</sup>CD71<sup>low</sup> cell-derived, 10-day-old 1° Endocrine/Acinar colonies gave rise to insulin<sup>+</sup>glucagon<sup>−</sup> and insulin<sup>−</sup>glucagon<sup>+</sup> cells as well as ductal and acinar cells (Fig. 7). These results demonstrate that CD133<sup>high</sup>CD71<sup>low</sup> cells are progenitor cells with tri-lineage differentiation capacity. An *in vivo* study reported by Thorel et al. (Thorel et al., 2010) showed that severe beta-cell injury (>99% destruction) led to the formation of insulin<sup>+</sup>glucagon<sup>+</sup> cells, followed by the appearance of insulin<sup>+</sup>glucagon<sup>−</sup> cells. Because the regenerated beta cells were lineage-traced from glucagon-expressing cells, it was concluded that alpha cells trans-differentiated into beta cells (Thorel et al., 2010). It is possible that CD133<sup>high</sup>CD71<sup>low</sup> cells described in this study differentiated into insulin<sup>+</sup>glucagon<sup>−</sup> cells *in vivo* via an insulin<sup>+</sup>glucagon<sup>+</sup> intermediate cell stage *in vitro*. However, further lineage tracing experiments are needed to test this hypothesis.

In summary, we report that adult pancreatic progenitor cells from B6, non-transgenic mice can be highly enriched using two cell-surface markers and live-cell sorting. Approximately 30 and 10-fold enrichment of PCFUs-Ring and 1° PCFUs-Endocrine/Acinar, respectively, in CD133<sup>high</sup>CD71<sup>low</sup> cells were achieved compared to unsorted cells. It should be noted that only *in vitro* self-renewal and multi-lineage differentiation by the CD133<sup>high</sup>CD71<sup>low</sup> cells are demonstrated in the current study, and these results do not prove that progenitor cells exist *in vivo* in the adult pancreas. Further confirmation will require examining multi-lineage reconstitution and self-renewal of CD133<sup>high</sup>CD71<sup>low</sup> cells

transplanted into an animal model with a severely injured pancreas. Finally, the results presented in this study have direct implications for *in vitro* generation of glucose-responsive beta-like cells to treat diabetes patients.

## 4. Materials and methods

### 4.1. Mice

C57BL/6J (donors; 2–4 months old) (The Jackson Laboratory, Bar Harbor, ME, USA) and NOD-SCID (recipients; 2 months old) (Charles River Laboratory, Wilmington, MA, USA) were used in this study. All mice were maintained under specific pathogen-free conditions, and animal experiments were conducted according to the Institutional Animal Care and Use Committee at the City of Hope.

### 4.2. Preparation of Single Cell Suspensions

Murine pancreata were dissected, cleared of fat tissue under a dissecting microscope, and rinsed three times in cold DPBS containing 0.1% bovine serum albumin, penicillin, and streptomycin (PBS/BSA). Whole pancreata, in a dry petri dish placed on ice, were chopped using spring scissors for approximately 2 min or until finely minced. The triturated tissue was transferred to a 15 ml conical tube, washed once, resuspended in PBS/BSA containing collagenase B (2–4 mg/ml) (Roche, Mannheim, Germany) and DNase I (2000 U/ml) (Calbiochem, Darmstadt, Germany), and incubated at 37 °C for 20 min to yield a mostly single cell suspension. To hasten the digestion, tissue was gently disrupted every 5–10 min using a 16G syringe needle. Cells were then washed twice in cold PBS/BSA supplemented with 2000 U/ml DNase I, which was used to prevent re-aggregation of dissociated cells, and filtered through a 40 µm nylon mesh (BD Biosciences, San Jose, CA, USA) before antibody staining. Between 3 and 5 million cells per pancreas can be recovered from adult B6 mice.

### 4.3. Flow Cytometry and Cell Sorting

Single cell suspensions were first incubated with anti-mouse CD16/32 (10 µg/ml) (BioLegend, San Diego, CA, USA) for 5 min on ice to diminish nonspecific binding. Biotin-conjugated anti-mouse CD133 (clone 13A4; 5 µg/ml) (eBioscience, San Diego, CA, USA) and phycoerythrin/Cy7 (PE/Cy7)-conjugated anti-mouse CD71 (clone R17217; 5 µg/ml) (BioLegend) antibodies were added to cells. Cells were incubated for 20 min on ice, washed twice, and then treated with streptavidin-labeled allophycocyanin (APC) (2 µg/ml) (BioLegend) for 15 min on ice, washed twice, and resuspended in PBS/BSA/DNase I containing DAPI (0.2 µg/ml). Control antibodies were biotin-conjugated rat immunoglobulin (Ig)G1 (5 µg/ml) (eBioscience) and PE/Cy7-conjugated rat IgG1 (5 µg/ml) (BioLegend). For Supplementary Figs. 1 & 2, fluorescein isothiocyanate (FITC)-conjugated anti-mouse TER119 (clone TER119; 5 µg/ml) (BioLegend) was added to the primary antibody mix. Flow cytometry analysis was performed on an Accuri C6 or an LSRFortessa Cell Analyzer (Becton Dickinson, San Jose, CA, USA). Acquired flow data were analyzed with software provided by Accuri or FloJo (TreeStar, Ashland, OR, USA). Cell sorting was performed on an Aria-special order research product (SORP) (Becton Dickinson). All analyses included an initial gating of forward (FSC) and side (SSC) scatter to exclude debris. In cell sorting experiments, doublets were excluded by gating out high pulse-width cells, and live cells were selected by DAPI negative staining (Supplementary Fig. 6). The purity of the sorted population was routinely >95%.

### 4.4. Colony Assays

Sorted cells were resuspended at a density of  $2.5 \times 10^3$  cells/well/0.5 ml for the Matrigel assay or  $2.5 \times 10^4$  cells/well/0.5 ml for the

laminin-hydrogel assay as described previously (Jin et al., 2013). Culture media contained DMEM/F12 media, 1% methylcellulose (Sinetsu Chemical, Tokyo, Japan), 50% conditioned media from mouse embryonic stem cell derived pancreatic-like cells, 5% fetal calf serum (FCS), 10 mmol/l nicotinamide (Sigma, St. Louis, MO, USA), 10 ng/ml human recombinant activin B, 0.1 nmol/l exendin-4 (Sigma), and 1 ng/ml vascular endothelial growth factor-A (VEGF) (Sigma). When indicated, either 5% Matrigel or 100 µg/ml of laminin hydrogel (Jin et al., 2013) was added to media to generate Ring or Endocrine/Acinar colonies, respectively. Cells were plated in 24-well ultra-low protein-binding plates (Corning, Corning, NY, USA) and incubated in a humidified 5% CO<sub>2</sub> atmosphere. Ring or Endocrine/Acinar colony numbers were counted 3 weeks or 10 days after plating, respectively. For serial re-plating experiments, individual Ring colonies were handpicked and dissociated into single cells by incubating with 0.25% trypsin-EDTA at 37 °C for 5 min, followed by gentle pipetting. Single cells were then re-plated in the Matrigel assay as described above.

#### 4.5. Conventional or microfluidic quantitative reverse transcription-polymerase chain reaction (qRT-PCR)

Total RNA extraction, reverse transcription, and conventional qRT-PCR analyses were performed as previously described (Jin et al., 2013). Duplicate samples were used in all analyses. Microfluidic qRT-PCR was performed using the BioMark™ 48.48 Dynamic Array system (Fluidigm, South San Francisco, CA, USA). Single colonies were lifted one by one from the methylcellulose-containing medium under direct microscopic visualization using a 10 µl Eppendorf pipette, collected in reaction buffer (10 µl), and pre-amplified (14 cycles) according to the manufacturer's instructions (Fluidigm). Amplified cDNA was loaded onto a 48.48 Dynamic Array using the NanoFlex integrated fluidic circuit (IFC) controller (Fluidigm). Threshold cycle (Ct), as a measure of fluorescence intensity, was determined by the BioMark PCR analysis software (Fluidigm) and expressed as a heat map or delta Ct compared to β-actin. All experiments were performed with negative (water) and positive (adult C57BL/6J pancreatic cells) controls. TaqMan probes (Life Technologies, Grand Island, NY, USA) and their catalog numbers are listed in Supplementary Table 2.

#### 4.6. Electron Microscopy

Single colonies were collected, pooled, and fixed in 2% glutaraldehyde + 0.1 M Cacodylate buffer [Na(CH<sub>3</sub>)<sub>2</sub>AsO<sub>2</sub>·3H<sub>2</sub>O; pH 7.2] at 4 °C overnight. Colonies were washed three times with 0.1 M Cacodylate buffer (pH 7.2), post-fixed with 1% OsO<sub>4</sub> in 0.1 M Cacodylate buffer for 30 min, and washed three times with 0.1 M Cacodylate buffer. The samples were then dehydrated, embedded in Eponate, and polymerized at 64 °C for 48 h. Ultrathin sections (70-nm thickness) were cut using a Leica ultramicrotome (Leica Biosystems, Wetzlar, Germany) with a diamond knife, transferred to 200-mesh EM grids, and stained with 2% uranyl acetate in 70% ethanol for 1 min followed by treatment with Reynold's lead citrate for 1 min. Electron microscopy was performed on a Tecnai 12 transmission electron microscope (FEI, Hillsboro, OR, USA) equipped with an Ultrascan 2 K CCD camera (Gatan, Pleasanton, CA, USA).

#### 4.7. Immunostaining

For frozen sections, prefixed-pancreata were cryoprotected in 30% sucrose in PBS, embedded in O.C.T. (Sakura Finetek, Torrance, CA, USA), and sliced at 10 µm thickness. For paraffin-embedded formalin-fixed tissues, samples were cut to 5 µm thickness, dewaxed in xylene bath for 15 min, rehydrated in ethanol, and antigens retrieved by heating in a microwave oven for 10 min in 200 ml of sodium citrate buffer. Samples were incubated with blocking buffer supplemented with 5% donkey serum and 0.1% TritonX-100 at 4 °C

overnight before addition of primary antibodies. For whole-mount immunohistochemistry, colonies were manually picked, pooled, fixed in 4% paraformaldehyde at 4 °C overnight, and incubated with blocking buffer supplemented with 5% donkey serum and 0.1% TritonX-100 at 4 °C overnight. Primary antibodies were as listed in Supplementary Table 3 and detected with donkey-raised secondary antibodies conjugated to Cy3, Cy5, DyLight488, or AlexaFluor647 (Jackson ImmunoResearch, West Grove, PA, USA). Images were captured on a Zeiss LSM510 META NLO Axiovert 200 M inverted microscope, and figures prepared with LSM Image Browser software (Carl Zeiss, Germany).

#### 4.8. In vitro glucose challenge assay and intracellular C-peptide measurement

Primary Endocrine/Acinar colonies were pooled and incubated overnight with Krebs-Ringer solution (KRBH; 129 mM NaCl, 4.8 mM KCl, 2.5 mM CaCl<sub>2</sub>, 1.2 mM KH<sub>2</sub>PO<sub>4</sub>, 1.2 mM MgSO<sub>4</sub>, 5 mM NaHCO<sub>3</sub>, 10 mM HEPES, 0.1% bovine serum albumin) containing 10% FCS and 2.5 mM D-glucose. The next day, colonies were washed three times with KRBH containing 2% FCS and 2.5 mM D-glucose and then sequentially incubated with 2.5 mM D-glucose, 16.7 mM D-glucose, and 16.7 mM D-glucose plus 10 mM theophylline (37 °C, 0.5 ml/well, 2 h). The C-peptide concentration in the buffer was measured using the murine C-peptide ELISA kit, U-Type (Shibayagi Co., Gunma, Japan), which has a detection limit of 30 pg/ml. The stimulation was expressed as the fold change of C-peptide concentrations in buffer from the second and third treatments compared to the first treatment of the same well. To measure intracellular C-peptide, cells were lysed in RIPA buffer (Sigma) and the resulting lysate was analyzed for levels of total protein by BCA protein assay (ThermoFisher Scientific, Waltham, MA, USA) and C-peptide by ELISA as described above.

#### 4.9. In vivo transplantation

Primary Endocrine/Acinar colonies were handpicked, pooled, and incubated in recovery solution (BD Bioscience) for 1 h on ice. Intact colonies released from the semisolid media were washed and collected for transplantation. NOD-SCID mice (8 week-old males) were injected with streptozotocin (STZ; 50 mg/kg body weight; freshly made in 0.05 M citrate buffer, pH 4.5) for 3 consecutive days to induce diabetes (Gerling et al., 1994). Hyperglycemia was defined as >200 mg/dl and measured by OneTouch Ultra2 glucometer (LifeScan, Milpitas, CA, USA) starting 1 week after the last STZ injection. Approximately 12,000 Endocrine/Acinar colonies were placed under the renal capsule per mouse (n = 2). Grafts were examined 5 weeks post-transplantation by immunohistochemical staining of formalin-fixed paraffin-embedded tissue sections.

#### 4.10. RNA-seq analysis

Reads were aligned to the mouse genome (build mm10). Reads per kilobase per million (RPKM) (Mortazavi et al., 2008) were calculated for RefSeq transcripts (Pruitt et al., 2012) using an expectation-maximization algorithm in Partek Genomics Suite (Version 6.6) (Partek, St. Louis, MI, USA) (Xing et al., 2006). RPKM values were then further normalized via log<sub>2</sub> transformation following the addition of a scaling factor of 0.1 (Warden et al., 2014). Fold-change values were calculated on a linear scale based on the least-squares mean. P values were calculated by one-way ANOVA using the normalized RPKM values. False discovery rate (FDR) values were calculated using the method of Benjamini and Hochberg (Benjamini & Hochberg, 1995). Transcripts were defined as differentially expressed if they showed a fold-change value higher than 1.5 and FDR lower than 0.05. Potential functional significance was assessed by Gene Ontology enrichment terms (Genomics Suite™) (Partek). Genes differentially expressed by the CD133<sup>high</sup>CD71<sup>low</sup>

compared to the CD133<sup>+</sup>CD71<sup>−</sup> cells are listed in Supplementary Table 1. Data were deposited to the repository system Gene Expression Omnibus.

#### 4.11. Statistical analysis

All values were shown as mean  $\pm$  standard deviation. Significance was determined by Student's two-tailed t-test and  $P < 0.05$  was considered significant.
